ABSTRACT

The problem of efficiently performing transformations from geocentric to geodetic coordinates has been addressed at previous DIS Workshops. This paper extends the work presented at the Fourteenth DIS Workshop. As a consequence of the new algorithm for geocentric to geodetic coordinate conversion, a subsequent conversion to Universal Transverse Mercator coordinates is made considerably more efficient. No additional trigonometric or square root evaluations are required and accuracy is not degraded.

INTRODUCTION

The Distributed Interactive Simulation (DIS)^{1,2} environment requires frequent transformations between the DIS standard coordinate system and other coordinate systems used at DIS nodes. When entities are maneuvering, this requirement induces substantial computational loads on both the sending and receiving nodes. One of the more stressing situations occurs when a point in the standard geocentric system is transformed to geodetic coordinates and subsequently to Universal Transverse Mercator (UTM) coordinates.

New algorithms have been developed that substantially increase the efficiency of the transformation from geocentric to geodetic coordinates^{3,4}. This note describes an extension of these algorithms that increases the efficiency of the transformation from geodetic to UTM coordinates. Results of this note should be applicable to

applications other than DIS where efficient transformations of the type addressed are required.

Background

The DIS program maintains a set of recommended standard algorithms for coordinate transformations at the Visual Systems Laboratory of the Institute for Simulation and Training (IST), University of Central Florida. Proposed new algorithms are sent to IST for testing in terms of efficiency and accuracy. The best of the current implementations for obtaining UTM coordinates is based on the transformation equations contained in a USGS Bulletin "Map Projections Used by the U. S. Geological Survey"⁵. These equations are written in a form that is readable, preserves accuracy and applies to all situations. However, the direct implementation of the equations, does not lead to an efficient implementation.

In the DIS environment, the conversion to UTM coordinates almost always follows a conversion from geocentric coordinates to geodetic coordinates. As a consequence, the trigonometric functions of latitude are available from the algorithm of references 3 and 4 and need not be re-computed. Likewise, the radius of curvature is also available. In addition, the UTM transformation equations involve trigonometric functions of integer multiples of the latitude. By utilizing multiple angle identities, these evaluations can be done without evaluating any trigonometric functions. These observations permit the transformation equations to be written in a form that allows maximal factorization of common factors and requires no square roots or trigonometric calculations. The resulting procedure is estimated to be on the order of fifty percent faster than the existing recommended DIS procedure.

The Transverse Mercator Coordinate System

The Transverse Mercator system is a conformal (angle preserving) projection of points relative to a geodetic Earth model onto a plane tangent to the geodetic surface at the intersection of the central meridian and the equator. Under this transformation both the central meridian and the equator map into straight lines. No other meridian or parallel maps to a straight line under this projection. While conformal mappings preserve angles other distortions are introduced as shown in Figure 1.

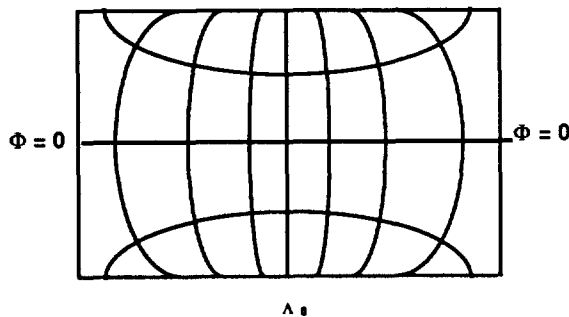

Figure 1

Meridians and parallels in the Transverse Mercator coordinate system.

As can be seen in the figure, the distortions are small near the origin and increase away from it. To minimize this distortion, the concept of a Universal Transverse Mercator (UTM) projection is introduced.

The Universal Transverse Mercator (UTM) Coordinate System

UTM coordinates are defined in the following manner. The Transverse Mercator projection is modified by introducing a set of longitudes spaced six degrees apart on the equator. Each of these points is used as a local origin for a Transverse Mercator projection. In essence, the central meridian is replaced by a set of meridians equally spaced around the equator. This spacing corresponds to a set of 60 UTM zones. In any one zone the Transverse Mercator projection becomes localized and distortions are minimized.

Transverse Mercator projections are defined with respect to a geodetic earth model, the associated rotating geocentric coordinate system and the corresponding geodetic coordinate system. A number of reference geodes have been used in astrogeodetic work⁶. These all have the form:

$$(1) \quad (X/a)^2 + (Y/a)^2 + (Z/c)^2 = 1.$$

Figure 2 below depicts the geometry of the geocentric (Cartesian) system and the geodetic system in three dimensions. The geocentric coordinates of a point P are (X,Y,Z) and the corresponding geodetic coordinates of P are (φ,λ,h) where φ is latitude, λ is longitude and h is the height above the reference ellipsoid. The line connecting the Z axis to P is orthogonal to the tangent plane at the point P_e.

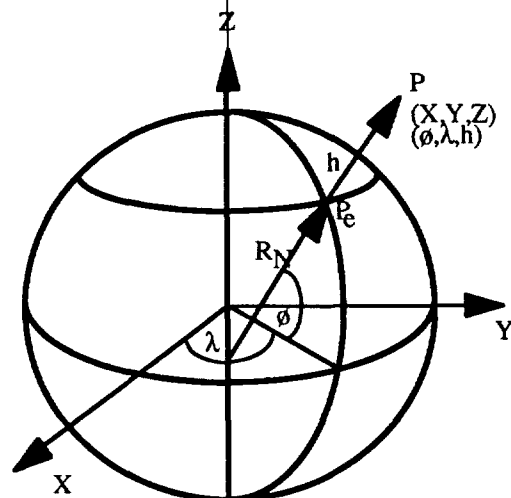

Figure 2

Cartesian and Geodetic Systems

The transformation from geodetic to geocentric coordinates is straightforward⁶ and is given by:

$$(2) \quad X = (R_N + h) \cos \phi \cos \lambda,$$

$$(3) \quad Y = (R_N + h) \cos \phi \sin \lambda,$$

$$(4) \quad Z = (R_N c^2 / a^2 + h) \sin \phi.$$

where R_N is the radius of curvature of the prime vertical and is given by

$$(5) \quad R_N = a / [1 - [\sin^2 \phi] (a^2 - c^2) / a^2]^{1/2}.$$

The inverse transformation is expressible in closed form,⁷ but this generally results in an inefficient implementation. An accurate and efficient iterative algorithm is contained in references 3 and 4.

The longitude λ is given by

$$(6) \quad \lambda = \tan^{-1} (Y / X),$$

where $-\pi \leq \lambda \leq \pi$.

Since the two minor axes of the geode are equal, the projection of the geode on any meridional plane defines an ellipse. The eccentricity of the ellipse is defined by

$$(7) \quad e^2 = (a^2 - c^2) / a^2.$$

It is convenient to define an additional constant e'^2 squared by

$$(8) \quad e'^2 = (a^2 - c^2) / c^2.$$

The flattening ratio f of the ellipse is defined by

$$(9) \quad f = (a - c) / a.$$

Reference 7 contains a good discussion of the process for transforming from geodetic to Transverse Mercator to UTM coordinates. In the appendix, the equations used in reference 5 and in the DIS standard code are summarized using notation consistent with references 3 and 4.

EFFICIENT TRANSFORMATION FROM GEODETIC TO UTM COORDINATES

The transformations given in the Appendix involve the sine of multiple angles. Most of the implementations of these equations and similar equations contained in reference 7 call the sine function repeatedly to evaluate the sine of each multiple angle. This is relatively costly in terms of processing time. The use of the well known multiple angle identities avoids the unnecessary

calls. However, multiple angle identities are not unique and some care is needed to pick a form that maximizes the factorability of the resulting equations. The variables used in this section are defined in the appendix. Accordingly the following are used:

$$(10) \quad \sin 2\phi = 2 \sin \phi \cos \phi,$$

$$(11) \quad \cos 2\phi = 1 - 2 \sin^2 \phi,$$

$$(12) \quad \sin 4\phi = 2 \sin 2\phi \cos 2\phi,$$

$$(13) \quad \sin 6\phi = 2 \sin 2\phi \cos^2 2\phi + \sin 2\phi (1 - 2 \sin^2 2\phi).$$

Using equations (12) and (13), equation (35) of the appendix can be written

$$(14) \quad M = a \{ A_0 \phi - \sin 2\phi [A_2 - 2 \cos 2\phi (A_4 - A_6 (1 - \sin^2 2\phi))] \}.$$

As previously noted, when UTM coordinates are needed in DIS applications they almost always follow a transformation from geocentric to geodetic coordinates. If the algorithms of reference 4 or 5 are used, the following are already computed using just square roots: $\sin \phi$, $\cos \phi$, $\sin^2 \phi$, $\cos^2 \phi$, $\tan \phi$ and R_N . These values can be used in an integrated routine that transforms from geocentric to geodetic, and on option, to UTM coordinates. Coupled with (10) to (13) the computation of M reduces to simple algebraic operations.

As shown in the appendix, the Transverse Mercator coordinates of a point, x_{TM} and y_{TM} , are computed prior to computing the UTM coordinates. The equations for x_{TM} and y_{TM} are polynomials in A . If these equations were coded as shown, optimizing compilers would automatically factor out common factors in A . Unfortunately, many of the existing implementations compute the powers of A and store them as constants prior to coding the polynomial. As a result, the compiler may not be able to recognize the common factors. To insure that the factorization occurs the equations should be written as follows,

$$(15) \quad x_{TM} = k_0 R_N A \{ 1 + A^2 [(1 - T + C)/6 + (5 - 18T + T^2 + 72C - 58 e'^2) A^2 / 120] \}.$$

$$(16) \quad y_{TM} = k_0 \{ M + R_N \tan \phi A^2 [1/2 + A^2 (5 - T + 9C + 4C^2) / 24 +$$

$$(61 - 58T + T + 600C - 330 \varepsilon^{-2}) A^2 / 720)]).$$

When a particular geode is used, further economies can be obtained by reformatting (14), (15) and (16). This reformatting also will insure that constants are not repeatedly computed. Accordingly, let

$$(17) \quad B_0 = ak_0 A_0,$$

$$(18) \quad B_2 = 2ak_0 A_2,$$

$$(19) \quad B_4 = 4ak_0 A_4,$$

$$(20) \quad B_6 = 4ak_0 A_6,$$

$$(21) \quad B_7 = B_4 - B_6,$$

$$(22) \quad B_8 = 4B_6,$$

$$(23) \quad v = \sin \phi \cos \phi,$$

$$(24) \quad u = \sin^2 \phi,$$

$$(25) \quad M_k = k_0 M.$$

With these definitions

$$(26) \quad M_k = B_8 \phi - v \{ B_2 - (1-2u)[B_7 + v^2 B_8] \},$$

$$(27) \quad x_{TM} = R_N A \{ k_0 + A^2 [(1-T+C)k_0 / 6 + (5-58 \varepsilon^{-2} - 18T + T^2 + 72C)A^2 k_0 / 120] \},$$

$$(28) \quad y_{TM} = \{ M + R_N \tan \phi A^2 [k_0 / 2 + A^2 ((5-T+9C + 4C^2)k_0 / 24 + (61-330 \varepsilon^{-2} - 58T + T^2 + 600C)A^2 k_0 / 720)] \},$$

where the terms $k_0 / 2$, $k_0 / 6$, $k_0 / 24$, $k_0 / 120$, $k_0 / 720$, $5 - 58 \varepsilon^{-2}$ and $61 - 330 \varepsilon^{-2}$ are pre-computed global constants.

RESULTS

Formal timing studies that compare the new formulation to the DIS standard have not yet been completed. The DIS standard code based on reference 5 was obtained from the Visual Systems Laboratory of the Institute for Simulation and Training, University of Central Florida during February of 1996. Operations counts were obtained

for each distinct call of the routine (global constants were ignored). Similarly, operations counts were obtained for the new algorithm (i.e. equations (23),(26),(27),(28),(32),(33),(34),(40),(42),(44) and (46).

The results are summarized in Table 1 below.

Table 1. Operations count for standard and new algorithm.

	DIS/IST	New Algorithm
Multiply	40	35
Add	23	22
Divide	6	0
Square Root	1	0
Sine or Cosine	5	0

In the presentation of reference 3 at the 13th DIS Workshop experimental data were presented indicating that square root function calls take approximately the same processing time as five floating point multiplies on machines equipped with floating point units. Similarly, the sine or cosine take the same time as five to twelve floating point multiplies, depending on the particular machine. If all the arithmetic operations in Table 1 are assumed to take the same time as a floating point multiply, estimates of relative execution time can be made.

The above analysis shows that the DIS/IST algorithm takes between 99 and 134 operations while the new algorithm takes 57 operations. The percent improvement is defined in terms of old time minus the new time divided by the old time. In such terms the estimated improvement ranges from 42 to 57 percent. These estimates may be conservative in that the DIS/IST procedure takes 46 long operations (multiply or divide) while the new algorithm takes only 35 and generally the long operations are more expensive in terms of computer time.

Howard Lu of SAIC in Boston has implemented an early version of the new algorithm and has found improvements in the same range as above. The author is indebted to Howard for communicating this information.

CONCLUSIONS

The algorithm proposed above is most suitable for DIS applications and may have utility in other compute intensive environments. The procedure should be readily adaptable to the standard UTM transformations that are contained in the Military Handbook (reference 7). These differ slightly from the transformations appearing in reference 5, in that more terms are used in some of the series approximations.

APPENDIX

The transformations from geodetic to Transverse Mercator coordinates are taken directly from reference 5. The mathematical form of the equations shown below corresponds exactly to that used in the reference. A few variable name changes are employed to make these equations correspond to the notation used in references 3 and 4.

Transformation from geodetic to Transverse Mercator

A point with geodetic coordinates (ϕ, λ, h) , where the angles are in radians, has Transverse Mercator coordinates (x_{TM}, y_{TM}) given by,

$$(29) \quad x_{TM} = k_0 R_N \{ A + (1 - T + C)A^3/6 + (5 - 18T + T^2 + 72C - 58\epsilon^2)A^5/120 \},$$

$$(30) \quad y_{TM} = k_0 \{ M + R_N \tan \phi (A^2/2 + (5 - T + 9C + 4C^2)A^4/24 + (61 - 58T + T + 600C - 330\epsilon^2)A^6/720) \},$$

where k_0 is the point scale factor and

$$(31) \quad \lambda_0 = \text{central meridian in radians,}$$

$$(32) \quad A = (\lambda - \lambda_0) \cos \phi,$$

$$(33) \quad T = \tan^2 \phi,$$

$$(34) \quad C = \epsilon^2 \cos^2 \phi,$$

$$(35) \quad M = a (A_0 \phi - A_2 \sin 2\phi + A_4 \sin 4\phi - A_6 \sin 6\phi),$$

$$(36) \quad A_0 = 1 - \epsilon^2/4 - 3\epsilon^4/64 - 5\epsilon^6/256,$$

$$(37) \quad A_2 = 3\epsilon^2/8 + 3\epsilon^4/32 + 45\epsilon^6/1024,$$

$$(38) \quad A_4 = 15\epsilon^4/256 + 45\epsilon^6/1024,$$

$$(39) \quad A_6 = 35\epsilon^6/3072.$$

The altitude h does not enter into the transformation to Transverse Mercator or to UTM coordinates.

Transformation from Transverse Mercator to UTM

The UTM projection differs from the Transverse Mercator projection as follows:

1. The longitude of each central meridian, in degrees, is given by $3 + 6n$, $n = 0, 1, \dots, 59$.
2. The point scale factor k_0 along the central meridian is 0.9996.
3. The northing coordinate y_{UTM} has an origin 0 at the equator for points in the northern hemisphere. The southing coordinate y_{UTM} has an origin equal to 10,000,000. meters at the equator for points in the southern hemisphere. Southing decreases as points move in the direction of the south pole.
4. The easting coordinate x_{UTM} , has its origin equal to 500,000. meters at the central meridian.

If the longitude λ is expressed in radians, the UTM zone is found from:

$$(40) \quad z = \text{Greatest Integer} \leq (31 + 180\lambda/(6\pi)),$$

for $0 \leq \lambda < \pi$.

$$(41) \quad z = \text{Greatest Integer} \leq (180\lambda/(6\pi) - 29),$$

for $\pi \leq \lambda < 2\pi$.

For each zone, the central meridian λ_0 , expressed in radians, is given by:

$$(42) \quad \lambda_0 = (6z - 183)\pi/180 \quad \text{for } z \geq 31,$$

or

$$(43) \quad \lambda_0 = (6z + 177)\pi/180 \quad \text{for } z \leq 30.$$

Once the zone has been identified and the central meridian computed, UTM coordinates are

computed, in meters, from Transverse Mercator coordinates by

$$(44) \quad X_{\text{UTM}} = X_{\text{TM}} + 500,000.$$

For points in the northern hemisphere,

$$(45) \quad Y_{\text{UTM}} = Y_{\text{TM}}.$$

For points in the southern hemisphere,

$$(46) \quad Y_{\text{UTM}} = Y_{\text{TM}} + 500,000.$$
